

# Chapter 8

## Polymorphism

Slides prepared by Rose Williams, *Binghamton University*

Kenrick Mock, *University of Alaska Anchorage*

## Introduction to Polymorphism

- There are three main programming mechanisms that constitute object-oriented programming (OOP)
  - Encapsulation
  - Inheritance
  - Polymorphism
- Polymorphism is the ability to associate many meanings to one method name
  - It does this through a special mechanism known as *late binding* or *dynamic binding*

# Introduction to Polymorphism

- Inheritance allows a base class to be defined, and other classes derived from it
  - Code for the base class can then be used for its own objects, as well as objects of any derived classes
- Polymorphism allows changes to be made to method definitions in the derived classes, *and have those changes apply to the software written for the base class*

# Late Binding

- The process of associating a method definition with a method invocation is called *binding*
- If the method definition is associated with its invocation when the code is compiled, that is called *early binding*
- If the method definition is associated with its invocation when the method is invoked (at run time), that is called *late binding* or *dynamic binding*

# Late Binding

- Java uses late binding for all methods (except **`private`**, **`final`**, and **`static`** methods)
- Because of late binding, a method can be written in a base class to perform a task, even if portions of that task aren't yet defined
- For an example, the relationship between a base class called **`Sale`** and its derived class **`DiscountSale`** will be examined

# The **`Sale`** and **`DiscountSale`** Classes

- The **`Sale`** class contains two instance variables
  - **`name`**: the name of an item (**`String`**)
  - **`price`**: the price of an item (**`double`**)
- It contains three constructors
  - A no-argument constructor that sets **`name`** to **`"No name yet"`**, and price to **`0.0`**
  - A two-parameter constructor that takes in a **`String`** (for **`name`**) and a **`double`** (for **`price`**)
  - A copy constructor that takes in a **`Sale`** object as a parameter

## The **Sale** and **DiscountSale** Classes

- The **Sale** class also has a set of accessors (**getName**, **getPrice**), mutators (**setName**, **setPrice**), overridden **equals** and **toString** methods, and a static **announcement** method
- The **Sale** class has a method **bill**, that determines the bill for a sale, which simply returns the price of the item
- It has two methods, **equalDeals** and **lessThan**, each of which compares two sale objects *by comparing their bills* and returns a **boolean** value

## The **Sale** and **DiscountSale** Classes

- The **DiscountSale** class inherits the instance variables and methods from the **Sale** class
- In addition,
  - it has its own instance variable, **discount** (a percent of the **price**), and
  - its own suitable constructor methods,
  - accessor method (**getDiscount**),
  - mutator method (**setDiscount**),
  - overriden **toString** method, and
  - static **announcement** method
- The **DiscountSale** class has its own **bill** method which computes the bill as a function of the **discount** and the **price**

## The **Sale** and **DiscountSale** Classes

- The **Sale** class **lessThan** method
  - Note the **bill()** method invocations:

```
public boolean lessThan (Sale otherSale)
{
  if (otherSale == null)
  {
    System.out.println("Error: null object");
    System.exit(0);
  }
  return (bill( ) < otherSale.bill( ));
}
```

## The **Sale** and **DiscountSale** Classes

- The **Sale** class **bill()** method:

```
public double bill( )
{
  return price;
}
```

- The **DiscountSale** class **bill()** method:

```
public double bill( )
{
  double fraction = discount/100;
  return (1 - fraction) * getPrice( );
}
```

## The **Sale** and **DiscountSale** Classes

- Given the following in a program:

```
. . .
Sale simple = new sale("floor mat", 10.00);
DiscountSale discount = new
           DiscountSale("floor mat", 11.00, 10);
. . .
if (discount.lessThan(simple))
  System.out.println("$" + discount.bill() +
                " < " + "$" + simple.bill() +
                " because late-binding works!");
. . .
```

  - Output would be:

```
$9.90 < $10 because late-binding works!
```

## The **Sale** and **DiscountSale** Classes

- In the previous example, the **boolean** expression in the **if** statement returns **true**
- As the output indicates, when the **lessThan** method in the **Sale** class is executed, it knows which **bill()** method to invoke
  - The **DiscountSale** class **bill()** method for **discount**, and the **Sale** class **bill()** method for **simple**
- Note that when the **Sale** class was created and compiled, the **DiscountSale** class and its **bill()** method did not yet exist
  - These results are made possible by late-binding

## Pitfall: No Late Binding for Static Methods

- When the decision of which definition of a method to use is made at compile time, that is called *static binding*
  - This decision is made based on the *type of the variable naming the object*
- Java uses static, not late, binding with **`private`**, **`final`**, and **`static`** methods
  - In the case of **`private`** and **`final`** methods, late binding would serve no purpose
  - However, in the case of a static method invoked using a calling object, it does make a difference

## Pitfall: No Late Binding for Static Methods

- The **`Sale`** class **`announcement()`** method:

```
public static void announcement( )
{
  System.out.println("Sale class");
}
```

- The **`DiscountSale`** class **`announcement()`** method:

```
public static void announcement( )
{
  System.out.println("DiscountSale class");
}
```

## Pitfall: No Late Binding for Static Methods

- In the previous example, the **`simple`** (**`Sale`** class) and **`discount`** (**`DiscountClass`**) objects were created
- Given the following assignment:

```
simple = discount;
```

  - Now the two variables point to the same object
  - In particular, a **`Sale`** class variable names a **`DiscountClass`** object

## Pitfall: No Late Binding for Static Methods

- Given the invocation:

```
simple.announcement();
```

- The output is:

```
Sale class
```

- Note that here, **`announcement`** is a static method invoked by a calling object (instead of its class name)
  - Therefore the type of **`simple`** is determined by its variable name, not the object that it references

## Pitfall: No Late Binding for Static Methods

- There are other cases where a static method has a calling object in a more inconspicuous way
- For example, a static method can be invoked within the definition of a nonstatic method, but without any explicit class name or calling object
- In this case, the calling object is the implicit **`this`**

## The **`final`** Modifier

- A *method* marked **`final`** indicates that it cannot be overridden with a new definition in a derived class
  - If **`final`**, the compiler can use early binding with the method

```
public final void someMethod() { . . . }
```

- A *class* marked **`final`** indicates that it cannot be used as a base class from which to derive any other classes

# Late Binding with `toString`

- If an appropriate **`toString`** method is defined for a class, then an object of that class can be output using **`System.out.println`**

```
Sale aSale = new Sale("tire gauge", 9.95);
System.out.println(aSale);
```

  - Output produced:

```
tire gauge Price and total cost = $9.95
```

- This works because of late binding

# Late Binding with `toString`

- One definition of the method **`println`** takes a single argument of type **`Object`**:

```
public void println(Object theObject)
{
   System.out.println(theObject.toString());
}
```

  - In turn, It invokes the version of **`println`** that takes a **`String`** argument
- Note that the **`println`** method was defined before the **`Sale`** class existed
- Yet, because of late binding, the **`toString`** method from the **`Sale`** class is used, not the **`toString`** from the **`Object`** class

## An Object knows the Definitions of its Methods

- The type of a class variable determines which method names **can be used** with the variable
  - However, the object named by the variable determines which definition with the same method name **is used**
- A special case of this rule is as follows:
  - The type of a class parameter determines which method names **can be used** with the parameter
  - The argument determines which definition of the method name **is used**

## Upcasting

- *Upcasting* is when an object of a derived class is assigned to a variable of a base class (or any ancestor class)

```
Sale saleVariable; //Base class
DiscountSale discountVariable = new
   DiscountSale("paint", 15,10); //Derived class
saleVariable = discountVariable; //Upcasting
System.out.println(saleVariable.toString());
```

- Because of late binding, **`toString`** above uses the definition given in the **`DiscountSale`** class

# Downcasting

- *Downcasting* is when a type cast is performed from a base class to a derived class (or from any ancestor class to any descendent class)
  - Downcasting has to be done very carefully
  - In many cases it doesn't make sense, or is illegal:

```
discountVariable =                  //will produce
     (DiscountSale)saleVariable;//run-time error
discountVariable = saleVariable //will produce
                                    //compiler error
```

  - There are times, however, when downcasting is necessary, e.g., inside the **`equals`** method for a class:

```
Sale otherSale = (Sale)otherObject;//downcasting
```

# Pitfall: Downcasting

- It is the responsibility of the programmer to use downcasting only in situations where it makes sense
  - The compiler does not check to see if downcasting is a reasonable thing to do
- Using downcasting in a situation that does not make sense usually results in a run-time error

# A First Look at the `clone` Method

- Every object inherits a method named **`clone`** from the class **`Object`**
  - The method **`clone`** has no parameters
  - It is supposed to return a deep copy of the calling object
- However, the inherited version of the method was not designed to be used as is
  - Instead, each class is expected to override it with a more appropriate version

# A First Look at the `clone` Method

- The heading for the **`clone`** method defined in the **`Object`** class is as follows:

```
protected Object clone()
```

# A First Look at the `clone` Method

- The heading for a **`clone`** method that overrides the **`clone`** method in the **`Object`** class can differ somewhat from the heading above
  - A change to a more permissive access, such as from protected to public, is always allowed when overriding a method definition
  - Changing the return type from **`Object`** to the type of the class being cloned is allowed because every class is a descendent class of the class **`Object`**
  - This is an example of a covariant return type

# A First Look at the `clone` Method

- If a class has a copy constructor, the **`clone`** method for that class can use the *copy constructor* to create the copy returned by the **`clone`** method

```
public Sale clone()
{
  return new Sale(this);
}
```

and another example:

```
public DiscountSale clone()
{
  return new DiscountSale(this);
}
```

## Pitfall: Sometime the `clone` Method Return Type is `Object`

- Prior to version 5.0, Java did not allow covariant return types
  - There were no changes whatsoever allowed in the return type of an overridden method
- Therefore, the **`clone`** method for all classes had **`Object`** as its return type
  - Since the return type of the clone method of the **`Object`** class was **`Object`**, the return type of the overriding clone method of any other class was **`Object`** also

## Pitfall: Sometime the `clone` Method Return Type is `Object`

- Prior to Java version 5.0, the **`clone`** method for the **`Sale`** class would have looked like this:

```
public Object clone()
{
  return new Sale(this);
}
```

- Therefore, the result must always be type cast when using a **`clone`** method written for an older version of Java

```
Sale copy = (Sale)original.clone();
```

## Pitfall: Sometime the `clone` Method Return Type is `Object`

- It is still perfectly legal to use Object as the return type for a clone method, even with classes defined after Java version 5.0
  - When in doubt, it causes no harm to include the type cast
  - For example, the following is legal for the clone method of the Sale class:

```
Sale copy = original.clone();
```

  - However, adding the following type cast produces no problems:

```
Sale copy = (Sale)original.clone();
```

## Pitfall: Limitations of Copy Constructors

- Although the copy constructor and **`clone`** method for a class appear to do the same thing, there are cases where only a **`clone`** will work
- For example, given a method **`badcopy`** in the class **`Sale`** that copies an array of sales
  - If this array of sales contains objects from a derived class of **`Sale`**(i.e., **`DiscountSale`**), then the copy will be a plain sale, not a true copy

```
b[i] = new Sale(a[i]); //plain Sale object
```

## Pitfall: Limitations of Copy Constructors

- However, if the **clone** method is used instead of the copy constructor, then (because of late binding) a true copy is made, even from objects of a derived class (e.g., **DiscountSale**):

```
b[i] = (a[i].clone());//DiscountSale object
```

  - The reason this works is because the method **clone** has the same name in all classes, and polymorphism works with method names
  - The copy constructors named **Sale** and **DiscountSale** have different names, and polymorphism doesn't work with methods of different names
